[초록 원문]

Generative world models offer controllable and repeatable closed-loop simulation for end-to-end and vision-language-action driving policies, but production deployment exposes three unresolved requirements: faithfully reproducing a mixed fisheye-pinhole rig at native resolutions; reconciling causal, per-timestep interaction with long-horizon stability and low latency; and preserving scene identity when a location is revisited. We present ZYT-World, a single architecture that natively generates four fisheye views with field of view $> 180^\circ$ and three pinhole views. Projection-specific Plucker adapters encode camera geometry, ego-motion adaptive layer normalization provides global motion control, and a lightweight pixel-aligned layout conditions traffic participants and signals through instance-level boxes, headings and colors. Heterogeneous training combines full-rig geometric coverage with high-resolution detail. Teacher forcing, causal consistency distillation, self-rollout distribution matching distillation, and RigCritic transform a 40-step bidirectional teacher into a one-step, per-latent streaming generator, with RigCritic evaluating the seven-view rig jointly. A 19M-parameter variational autoencoder decoder

(TinyVAE), W8A8 quantization, and our inference engine reduce decoding, backbone, and incremental-execution costs, respectively. Finally, cross-trajectory pairs derived from real captures train a plug-in implicit-memory module that preserves place-specific evidence. On the internal multi-view test set, the one-step model retains more than 90% of the teacher's PSNR and SSIM, while FID, FVD, and LPIPS stay within 11% of the teacher. Under the generator-only timing in Figure 2, it is 107.7 times faster than the 40-step bidirectional teacher. TinyVAE decodes 59.8 times faster than Wan. 30s rollouts and cross-trajectory revisits show the intended long-horizon and memory behavior.

ZYT-World: A Real-Time Controllable World Model for Closed-Loop Autonomous-Driving Simulation ZYT AI Team

Generative world models offer controllable and repeatable closed-loop simulation for end-to-end and vision-language-action driving policies, but production deployment exposes three unresolved requirements: faithfully reproducing a mixed fisheye-pinhole rig at native resolutions; reconciling causal, per-timestep interaction with long-horizon stability and low latency; and preserving scene identity when a location is revisited along a different trajectory. We present ZYT-World, a single architecture that natively generates four fisheye views with field of view (FoV) $> 180^\circ$ and three pinhole views. Projection-specific Plücker adapters encode camera geometry, ego-motion adaptive layer normalization (AdaLN) provides global motion control, and a lightweight pixel-aligned layout conditions traffic participants and signals through instance-level boxes, headings, colors, and directions. Heterogeneous training combines full-rig geometric coverage with high-resolution detail. Teacher forcing (TF), causal consistency distillation (CD), self-rollout distribution matching distillation (DMD), and RigCritic transform a 40-step bidirectional teacher into a one-step, per-latent streaming generator, with RigCritic evaluating the full seven-view rig jointly. A 19M-parameter variational autoencoder decoder (TinyVAE), W8A8 quantization, and our inference engine reduce decoding, backbone, and incremental-execution costs, respectively. Finally, cross-trajectory pairs derived from real captures train a plug-in implicit-memory module that preserves place-specific evidence when a location is revisited. On the internal multi-view test set, the one-step model retains more than 90% of the teacher's PSNR and SSIM, while FID, FVD, and LPIPS stay within 11% of the teacher. Under the generator-only timing in Figure 2, it is $107.7\times$ faster than the 40-step bidirectional teacher. TinyVAE decodes $59.8\times$ faster than the Wan decoder. 30 rollouts and cross-trajectory revisits show the intended long-horizon and memory behavior. Videos and additional results are available at zyt-aim.github.io/ZYT-World.

1 Introduction

End-to-end and vision-language-action driving policies require controllable, repeatable, and affordable closed-loop evaluation. Road testing is expensive and sparsely samples safety-critical long-tail events, whereas open-loop metrics cannot capture compounding interaction errors. A generative world model instead synthesizes multi-view observations from visual history and planned ego-motion and alternates with the policy in the simulation loop [1, 20, 28, 56]. ZYT-World conditions on per-timestep pose increments; raw control commands must first be mapped into this representation.

1.1 Four requirements for a closed-loop world model

Because generated observations directly feed the policy, closed-loop utility depends on four capabilities. Sensor interchangeability. Camera count, projection, calibration, native resolution, and pixel statistics should match the production rig so domain gaps do not enter the policy as perception errors. Motion response and scene control. Each step depends only on history and current ego-motion, while roads, agents, and traffic lights remain editable for counterfactual long-tail scenarios. 1

arXiv:2609.21712v1 [cs.CV] 18 Sep 2026 Spatiotemporal consistency. Geometry and layout must remain coherent across views, long rollouts, and revisits along different trajectories. Real-time deployability. Generation plus decoding must fit the policy control period under a fixed compute budget. We report generator and decoder speedups separately; real-time throughput is 4 FPS for the full seven-view rig on the two-GPU setup in Figure 1. Left fisheye Front fisheye Right fisheye Rear fisheye Rear view 4× FISHEYE FOV > 180° + 3× PINHOLE native heterogeneous resolutions FRAME-WISE AUTOREGRESSIVE causal streaming generation PLUG-IN MEMORY MODULE long-horizon consistency on revisits 1-STEP DISTILLATION one denoising step per latent 2 GPU · 4FPS / 7 VIEW real-time streaming inference MINUTE-SCALE ROLLOUT stays coherent for minutes Real worlds, in real time. 0 s 1 s 2 s 4 s 6 s 30 s Front wide Front narrow Figure 1 Native seven-view mixed fisheye-pinhole generation under per-latent, one-step, bounded-history rollout: 4 FPS for the full seven-view rig on two GPUs. Per-metric trade-offs are in Sec. 7.2. Prior driving world models address autoregressive prediction, controllable multi-view diffusion, and longhorizon extrapolation [10, 13, 19, 24, 35, 36, 38, 43, 53]. CausVid, Self Forcing, Causal Forcing++, ASD, One-Forcing, and AAD-1 further reduce the sampling cost of successive autoregressive units to a few steps or one step [6, 14, 18, 45, 49, 54]. ZYT-World targets the production setting in which four capabilities must coexist: native heterogeneous sensing, per-timestep control, cross-trajectory memory, and one-step streaming generation. Table 1 places it against public driving world models along these axes. 2

[초록 원문]

Third-party adapters for open-weight language models ship as opaque weight matrices; a recipient cannot check whether an adapter hides a backdoor without trusting the publisher or inspecting the weights, the publisher's core asset. For one important class (payloads placed where a safety monitor is structurally blind), detection is unsound as a defense: every detector that factors through the declared monitor is invariant on its blind subspace, and honest and backdoored adapters overlap on every blind-subspace statistic we evaluate, because benign adaptation uses that subspace too. Rather than detect this channel, we make it structurally ~~W~~emph{absent} and prove that we did. The publisher builds the adapter to read the input only through directions the monitor covers and proves this in zero knowledge, revealing nothing about the read factor it certifies. The certificate is cheap because the expensive part, identifying the monitor's blind spot, is a deterministic function of the ~~W~~emph{public} base model, so only one linear identity is proved; the served residual is the base model's own public floor, not a prover-chosen tolerance. The result is ~~W~~emph{ServeGuard}, a supply-chain primitive: the publisher ships a ~~W~~emph{proof-carrying adapter} whose proof lets a consumer or regulator verify, without the certified read factor and without trusting the publisher, that the adapter carries no hidden channel of this class relative to the declared monitor; an admission-time typing guard binds the guarantee to the adapter bytes admitted at serving time. Across eight checkpoints up to 7B from four families, the monitoring budget is architectural: the measured frontier saturates at the value-path rank on grouped-query checkpoints but not on multi-head ones. On a 0.5B model confinement is nearly free for benign adaptation, making monitor quality the security lever.

Third-party adapters for open-weight language models ship as opaque weight matrices; a recipient cannot check whether an adapter hides a backdoor without trusting the publisher or inspecting the weights, the publisher's core asset. For one important class (payloads placed where a safety monitor is structurally blind), detection is unsound as a defense: every detector that factors through the declared monitor is invariant on its blind subspace, and honest and backdoored adapters overlap on every blind-subspace statistic we evaluate, because benign adaptation uses that subspace too. Rather than detect this channel, we make it structurally absent and prove that we did. The publisher builds the adapter to read the input only through directions the monitor covers and proves this in zero knowledge, revealing nothing about the read factor it certifies. The certificate is cheap because the expensive part, identifying the monitor's blind spot, is a deterministic function of the public base model, so only one linear identity is proved; the served residual is the base model's own public floor, not a prover-chosen tolerance. The result is ServeGuard, a supply-chain primitive: the publisher ships a proof-carrying adapter whose proof lets a consumer or regulator verify, without the certified read factor and without trusting the publisher, that the adapter carries no hidden channel of this class relative to the declared monitor; an admission-time typing guard binds the guarantee to the adapter bytes admitted at serving time. Across eight checkpoints up to 7B from four families, the monitoring budget is architectural: the measured frontier

saturates at the value-path rank on grouped-query checkpoints but not on multi-head ones. On a 0.5B model confinement is nearly free for benign adaptation, making monitor quality the security lever. 1 Introduction Third-party model components ship as weights, and the supply chain that moves them (fine-tuning services, model hubs, vendor releases, and the regulators who must vet them) has no way to check what those weights carry. A fine-tuning service returns an adapter; a model hub serves a checkpoint; a vendor delivers a quantized release. The recipient runs the artifact inside a safety pipeline and wants assurance that it carries no hidden backdoor; the recipient's own stakeholders (consumers, regulators, auditors) may require that assurance without direct access to the model. Three options exist today, and each fails. Benchmark scores say nothing about a payload that activates only on a 1 arXiv:2609.21515v1 [cs.CR] 18 Sep 2026 trigger. Full weight disclosure exposes the publisher's intellectual property, and even then a weight matrix is not human-interpretable the way source code is. Third-party audit under non-disclosure relocates trust to the auditor rather than removing it. The recipient is left to trust the publisher. What can hide. We study one precisely characterized channel class. In a transformer attention layer, each token's representation passes through three learned projections: the query and key maps, which determine which tokens attend to which, and the value map, which determines what information is read. Deployed safety monitors read the internal state through a fixed linear feature map: a probing classifier scores the residual stream through learned weights [3], a representation engineering defense watches the projection onto a declared refusal or harmfulness direction [2, 50], and an attention-pattern monitor such as Attention Tracker [25] post-processes the query/key features of selected heads. The post-processing may be nonlinear; what the certificate is defined against is the linear feature map, which is public once the operator declares what it watches, and a payload in the feature map's kernel leaves every downstream statistic unchanged. A monitor that inspects only the query/key side has a blind subspace: perturbations it maps to zero and therefore cannot distinguish from no perturbation at all. Such a perturbation is invisible to every test that queries only the monitor's output, at every payload strength, yet the value path reads it. The channel is invisible by construction, not by stealth, and it can be shipped as a LoRA adapter (a small, low-rank weight update added to a pretrained model). The security-relevant property is thus not the harm a particular payload causes but the invisibility: no detector that factors through the declared monitor can observe a kernel payload, and blind-space occupancy is not a sound reference-free discriminator of benign from payload-carrying adapters (Section 7), so the principled defense is to make the channel structurally absent, not to bound the payload in hand. Why detection fails. The first instinct is to detect the channel from the released weights. It is uninformative. The monitor's blind subspace occupies most of the residual stream (the hidden-state vector passed between layers; 640 of 768 dimensions on GPT-2 [37]), so any low-rank adapter places the bulk of its computation there by geometry alone: a trained honest adapter and a backdoored one are indistinguishable on every kernel-activity statistic we evaluate (Section 7). This is not an artifact of a weak test: backdoors can be planted so as to be provably undetectable from the weights under explicit hardness assumptions [10, 18], with latent-space constructions resisting the known defenses [15]; absent a declared reference direction, weight-space detection has no sound target. Crucially, the no-go forbids distinguishing a backdoored model from a clean one without a reference; it does not forbid certifying a structural relation relative to a public, declared monitor. That distinction is the opening. The pivot: build it out and prove ... [앞부분 텍스트 일부 생략]

[초록 원문]

Edge AI accelerators are increasingly deployed in safety-critical environments, where model outputs may control physical actuators, make access-control decisions, or trigger alarms. In these settings, runtime failures often remain undetected because model corruption, distribution shift, and adversarial inputs can still produce well-formed, confident predictions. This paper presents TERMon, a lightweight hardware runtime monitor that detects such anomalies by observing inference behavior rather than re-executing or formally verifying the model. TERMon represents class-conditional trusted behavior as hardware-efficient ternary patterns that are matched in parallel against a thermometer-encoded fingerprint. The ternary encoding reproduces the corresponding unquantized range decision exactly. TERMon detects harmful weight corruptions in proportion to their behavioral impact, while out-of-distribution and adversarial inputs are largely not separable using the monitored features at a strict false-positive operating point. We implemented TERMon on a PYNQ-Z2 FPGA, and the pipelined design requires no on-chip block RAM or DSPs and has a two-cycle decision latency.

1 Introduction

Machine-learning (ML) models are increasingly deployed at the edge to perform inference across industrial sensing, autonomous systems, medical devices, space systems, and smart infrastructure [5, 16, 31]. Unlike models used for retrospective data analysis, This work is licensed under a Creative Commons Attribution 4.0 International License. AISec '26, The Hague, Netherlands ©2026 Copyright held by the owner/author(s). ACM ISBN 979-8-4007-3031-3/2026/11 <https://doi.org/10.1145/3847352.3848113> these models produce outputs that can directly control actuators, determine access, or trigger alarms. An incorrect prediction issued with high confidence can therefore lead to a safety or security incident. The main challenge is that many runtime failures produce no explicit execution error: the model continues to return syntactically valid, often high-confidence outputs even when the computation, the input distribution, or the input itself should no longer be trusted [8, 23]. This silent-failure behaviour spans several threat classes. Physically exposed edge hardware is vulnerable to memory faults and fault-injection attacks that corrupt stored model weights while leaving the surrounding software stack apparently intact [15, 25]. Deployed sensors may age, degrade, or drift outside their intended operating conditions, causing the model to receive out-of-distribution (OOD) inputs to which deep neural networks (DNN) may assign unjustified confidence [10, 22]. Adversarial examples pose a further concern, as carefully crafted inputs can change the model decision while remaining close to benign inputs [7, 20]. Existing defenses address parts of this problem, but they differ in their assumptions about what must be checked and when a system should respond. Weight-integrity checks are well suited when every modification of stored weights must be detected. However, in deployments where recovery is costly, such as space systems or remote sensing platforms, halting execution or restoring the model after every detected bit flip may be unnecessarily expensive when the corruption does not affect inference behavior. Software anomaly and OOD detectors can examine detailed runtime model behavior, but they are less isolated from the software stack they monitor and cannot guarantee a fixed hardware-level response. Their response may therefore be delayed by system load or disrupted if the software is compromised. A hardware monitor can instead provide deterministic, fixed-latency response independently of software scheduling. This motivates a lightweight hardware mechanism that checks whether the model's observed inference behavior remains within the ranges learned from an uncorrupted model. This paper proposes TERMon, a Ternary Envelope Runtime Monitor that detects runtime anomalies by observing inference behavior rather than re-executing or

formally verifying the model. TERMon monitors eight scalar features extracted from the input, intermediate activations, and output distribution, and checks them against ranges learned from clean inferences. A clean inference denotes an inference performed with an uncorrupted model on an in-distribution, non-adversarial input. TERMon does not identify the threat type or correct the model. Instead, it flags inferences whose monitored behavior deviates from the learned clean ranges. TERMon is designed for lightweight hardware implementation. Each feature is quantized, and thermometer encoded so that its arXiv:2609.21713v1 [cs.CR] 18 Sep 2026 AISec '26, November 15-19, 2026, The Hague, Netherlands Arish Sateesan and Edlira Dushku trusted range maps to a ternary pattern with fixed and don't-care positions. This allows the runtime decision to be implemented as a compact ternary content-addressable memory (TCAM)-compatible match. For persistent threats, such as corrupted weights or sensor drift, TERM ...
